

Conditional mean extinction time versus deterministic oscillation period

Each point is one R0–K–r grid cell; K is not included in the regression
Dashed black line: overall unweighted log–log regression; $T_{osc} < 50$

Conditional mean extinction time among extinct runs

T_{osc} depends on R0 and r under the current two–state formula, not K; different K values therefore share x–coordinates.
All grid cells are separate regression observations. Response is conditional on extinction within $t_{max} = 200$; only $T_{osc} < 50$ is analysed.
